## Abstract

A selected ion flow tube (SIFT) has been used to study the reactions of  $S_2^+$  with a series of organic molecules (as well as  $H_2$ , CO,  $NH_3$ , NO and  $NO_2$ ). These include the hydrocarbons,  $C_2H_4$ ,  $C_2H_6$ ,  $CH_2CCH_2$ ,  $CH_3CHCH_2$  and  $C_3H_8$ ; alcohols and thiols,  $CH_3OH$ ,  $C_2H_5OH$ ,  $CH_3SH$  and  $C_2H_5SH$ ; ethers  $(CH_3)_2O$  and  $(C_2H_5)_2O$ ; aldehydes and ketones,  $CH_3CHO$ ,  $C_2H_5CHO$  and  $(CH_3)_2CO$ ; and carboxylic acids and esters,  $HCO_2H$ ,  $HCO_2CH_3$ ,  $HCO_2C_2H_5$ ,  $CH_3CO_2H$ ,  $CH_3CO_2CH_3$ ,  $CH_3CO_2C_2H_5$ ,  $C_2H_5CO_2H$ ,  $C_2H_5CO_2CH_3$  and  $C_2H_5CO_2C_2H_5$ . The rate coefficients are generally close to the collisional values, with exceptions among the reactions involving the smaller molecules. Most prevalent are abstraction reactions leading to formation of the thiosulfeno radical,  $HS_2$ , or its protonated form; three-body associations; and channels leading to formation of the acetyl and propionyl cations,  $CH_3CO^+$  and  $C_2H_5CO^+$ , respectively. Only in reactions involving the alkenes is cleavage of the S–S bond of  $S_2^+$  observed. The isomeric molecules in the data set generally react very differently, as would be expected from reactivity controlled by the position and complexity of the functional groups. The data are discussed in terms of reaction mechanisms, thermodynamics, and implications for interstellar chemistry. © 1997 Elsevier Science B.V.

**Keywords:** Rate coefficients; Energetics; Ion-molecule reactions; Interstellar chemistry; Sulfur dimer cation

## 1. Introduction

Although the reactions of  $S^+$  ions have been extensively studied [1–3], very few reactions of  $S_n^+$

( $n \geq 2$ ) have been investigated [2–5]. The  $S^+$  reactions were studied mainly because of their significance to interstellar molecular synthesis; 15 of the  $> 100$  molecules detected in interstellar clouds contain sulfur (CS, NS, SiS,  $H_2S$ ,  $SO_2$ , OCS,  $H_2CS$ , HNCS,  $CH_3SH$ ,  $C_2S$ ,  $C_3S$ , SO,  $SO^+$ ,  $HCS^+$  and  $C_5S$  (detection uncertain)) [6].  $S^+$  has been calculated to have a moderately large abundance in dense clouds ( $> 10^4 \text{ cm}^{-3}$   $H_2$  density)

\* Corresponding author.

E-mail: adams@sunchem.chem.uga.edu

[1] and is particularly significant in diffuse clouds ( $\sim 100 \text{ cm}^{-3}$  of  $\text{H}/\text{H}_2$ ) since S-atoms can be ionized by the starlight which penetrates these regions (wavelengths corresponding to energies less than the ionization potential of H-atoms ( $\text{IP} = 13.6 \text{ eV}$ )) [7]. Since  $\text{S}^+$  is unreactive with the two most abundant molecules,  $\text{H}_2$  and  $\text{CO}$  (rate coefficients,  $k$ , of  $< 1(-14)$  and  $< 5(-13) \text{ cm}^3 \text{ s}^{-1}$  respectively) and also with  $\text{CO}_2$  and  $\text{H}_2\text{O}$  [3,8], it is available to react with other species such as the observed  $\text{H}_2\text{S}$  and  $\text{OCS}$  by the rapid reactions

and

with overall rate coefficients  $k = 8.2(-10)$  and  $9.1(-10) \text{ cm}^3 \text{ s}^{-1}$ , respectively [3,8]. A third pathway to the formation of  $\text{S}_2^+$  from observed interstellar species is

with a rate coefficient of  $k = 1.3(-9) \text{ cm}^3 \text{ s}^{-1}$  [3]. Thus, a reservoir of  $\text{S}_2^+$  is created, the reactions of which can then contribute to the chemistry. In the relatively few reactions that have been studied previously,  $\text{S}_2^+$  has been found to be unreactive with  $\text{H}_2$ ,  $\text{N}_2$ ,  $\text{O}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{N}_2\text{O}$  and  $\text{CH}_4$ , although there is some minor reactivity, reported in the literature, with  $\text{NO}$ ,  $\text{NO}_2$  and  $\text{NH}_3$  ( $k = 7.1(-12)$ ,  $3.5(-10)$  and  $1.5(-12) \text{ cm}^3 \text{ s}^{-1}$ , respectively) [4,5]. A small number of  $\text{S}_n^+$  reactions with  $n = 3-8$  have also been studied [4,5]. Note that  $\text{H}_2\text{S}^+$  and  $\text{S}_2$  have been discovered in the comet Araki-Alcock [9], and thus photoionization to produce  $\text{S}_2^+$  is bound to occur in this photon-rich environment.

In the present investigations, a comprehensive study of  $\text{S}_2^+$  reactions has been made with a series of 28 molecules varying in complexity from dia-

tomics to those containing 17 atoms, representing several of the important functional groups of organic molecules. This series includes hydrocarbons, alcohols and thiols, ethers, aldehydes, the ketone acetone, carboxylic acids and their methyl and ethyl esters. Fourteen of these species, viz.  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{NO}$ ,  $\text{NH}_3$ ,  $\text{C}_2\text{H}_4$ ,  $(\text{CH}_3)_2\text{CO}$ ,  $\text{CH}_3\text{OH}$ ,  $\text{C}_2\text{H}_5\text{OH}$ ,  $\text{CH}_3\text{SH}$ ,  $\text{CH}_3\text{CHO}$ ,  $(\text{CH}_3)_2\text{O}$ ,  $\text{HCO}_2\text{H}$ ,  $\text{HCO}_2\text{CH}_3$  [6,10] and, most recently,  $\text{CH}_3\text{CO}_2\text{H}$  [11], have been detected in the interstellar medium. The ionization potential of  $\text{S}_2$  has been determined by Liao and Ng to be 9.356 eV and is quite small, with the  $\text{S}_2^+$  bond energy being 5.376 eV [12]. Thus, in most of the cases considered in the present study, charge transfer is not energetically possible. In these cases, the reactions show a high propensity for association and for hydride abstraction.

## 2. Experimental

The details of selected ion flow tubes of the type used for these studies have been presented previously [13] and will only be briefly reviewed here. The  $\text{S}_2^+$  ions were generally produced in a low-pressure electron-impact ion source containing  $\text{CS}_2$ . The details of the mechanism for the production of  $\text{S}_2^+$  from this molecule have been discussed by several authors [14–16].  $\text{S}_2^+$  ions were selected by a quadrupole mass filter from the  $\text{CS}_2^+$ ,  $\text{S}_2^+$ ,  $\text{CS}^+$ ,  $\text{CS}_2^{2+}$ ,  $\text{S}^+$  and  $\text{C}^+$  ions issuing from the source and focused through a 1-mm hole into the flow tube. The selected  $\text{S}_2^+$  ions then flowed with the He carrier gas at a pressure of  $\sim 0.5$  torr to a detection quadrupole mass spectrometer/ion counting system at the downstream end of the flow tube. On injection, there was about 2–3% collisional fragmentation to produce  $\text{S}^+$ . Where it was significant, the products of the reactions of this  $\text{S}^+$ , which occurred in parallel with the  $\text{S}_2^+$  reactions, were determined in a separate study (to be published elsewhere) and their effects were accounted for in the ion product distribution of the  $\text{S}_2^+$  reaction. In general, no attempt was made to completely discriminate against injected ions containing the  $^{33}\text{S}$  and  $^{34}\text{S}$  isotopes of  $^{32}\text{S}$  since these are only 0.8 and 4.4%

of the major isotope, respectively. Indeed, in some cases the presence of product ions containing these isotopes enabled the elemental composition of a contentious product ion to be unambiguously determined (e.g.  $C_2H_4S_2^+$  rather than  $C_2H_4SO_2^+$  as a product in the  $S_2^+$  reaction with  $HCO_2C_2H_5$ ).

The small amount of break-up on injection suggests that there may have been some excitation of the  $S_2^+$ . From their collision-induced dissociation study of  $S_2^+$  and  $CS^+$  generated from  $CS_2$ , Kumar et al. [15] determined that  $S_2^+$ , formed in a high-pressure electron-impact source at 0.05–0.1 torr of  $CS_2$ , is effectively collisionally quenched to the ground electronic state. Checks for excitation in the  $S_2^+$  were made in the present work using a high-pressure electron impact source containing  $CS_2$  at  $\sim 0.2$ – $0.3$  torr. No difference in reactivity of  $S_2^+$  generated in the high-pressure source versus the low-pressure source was observed. Some quenching of any vibrational excitation would occur in the  $\sim 10^5$  collisions with He between injection of the  $S_2^+$  and injection of the neutral reactant. All of the decays of  $S_2^+$  were very linear, even for the slower reactions (e.g.  $S_2^+ + C_2H_6$ ), indicating the presence of only one ionic state, presumably the ground vibronic state. Also, no significantly endothermic reaction channel, which would be an indicator of excitation, was observed in this study. As a further check, in some cases  $N_2$  was added upstream as an additional quenchant. No effects due to excitation were detected.

Reactant gases and vapors were added at various points along the flow tube to give appropriate reaction lengths. The flows of these reagents were measured from the pressure drop across a calibrated capillary tube for either the undiluted gases or vapors, or in the cases of  $HCO_2H$ ,  $CH_3CO_2H$  and  $C_2H_5CO_2H$ , for dilute mixtures of the vapors in He (the pressure of the vapor was kept below its saturation vapor pressure and admixed with He at a pressure of  $\sim 950$  torr). The reaction with  $CH_3CO_2H$  was also studied with the undiluted vapor, and identical results were obtained. Viscosities of the permanent gases were taken from the literature [17], and vapor viscosities of the liquid reagents were measured using the pressure drop in a calibrated volume

evacuated through a calibrated capillary; viscosities determined in this manner are accurate to  $\pm 5\%$ , and generally show excellent agreement with available literature values [18]. Reactant gases were used without further purification and reactant vapors were further purified by freeze-pump-thaw cycles before use. The reaction rate coefficients and ion product distributions were determined in the usual way [19,20]. The rate coefficients are considered to be accurate to  $\pm 20\%$  in general, with the error increasing to  $\pm 30\%$  for sticky gases and reactant vapors. For the reagents which exist as mixtures of molecular monomers and dimers in the gas phase (i.e.  $NO_2$ ,  $HCO_2H$ ,  $CH_3CO_2H$  and  $C_2H_5CO_2H$ ), the true monomer flows were calculated from the measured reagent flows using literature equilibrium constants [21–23]; typical monomer flows were 1.37, 1.77, 1.88, and 1.82 times the measured flows for  $NO_2$ ,  $HCO_2H$ ,  $CH_3CO_2H$ , and  $C_2H_5CO_2H$ , respectively. Ion product distributions are accurate to  $\pm 5$  in the percentage. All measurements were conducted at  $298 \text{ K} \pm 4 \text{ K}$ .

An example illustrating the quality of the data is given in Fig. 1a and b. Fig. 1a shows that the decay of the  $S_2^+$  count rate with increasing  $CH_3SH$  flow has excellent linearity over more than two orders of magnitude change in the count rate. A small charge transfer channel is apparent which is due to the reaction of the small percentage of the fragment ion  $S^+$  [2]. The percentages of the primary and secondary products are plotted as a function of  $CH_3SH$  flow in Fig. 1b and the ion product distribution for the primary reaction obtained by extrapolating to zero flow. It can be seen that the  $CH_3SH_2^+$  and  $C_2H_5S^+$  are products of the secondary reaction of  $CH_3S^+$  with  $CH_3SH$  and that the  $CH_3SH^+$  contribution corresponds to the percentage of the  $S^+$  impurity ion. Where mass discrimination in the detection system was significant, it was accounted for in the manner described by Matthews et al. [24]. Thus, the primary product of the  $S_2^+$  reaction is  $CH_2SH^+ / CH_3S^+$ , i.e.

Note the neutral product  $\text{HS}_2$  which is very common in these  $\text{S}_2^+$  reactions.

### 3. Results and discussion

Data such as those presented in Fig. 1a and b have been used to construct the list of rate coefficients and ion product distributions in Table 1. The data are arranged by the functional class of the reactant neutral. There is consistent behavior throughout the data set independent of the ionization potential of the reactant. Product channels with  $\text{HS}_2$  as the probable neutral product are common, as is association. The rate coefficients quoted where there is an association channel are the binary rate coefficients at a pressure of  $\sim 0.5$  torr. In many of the cases, especially for the more complex reactant neutrals, the rate coefficients are large for association and thus are expected to be pressure-saturated [29]. For the cases where the association is slower ( $\text{C}_2\text{H}_4$ ,  $\text{HCO}_2\text{H}$ ), determination of the effective binary rate coefficient as a function of pressure should yield the ternary rate coefficient. Where there is competition between binary and ternary channels (e.g.  $\text{HCO}_2\text{C}_2\text{H}_5$ ,  $\text{CH}_2\text{CCH}_2$ ), pressure dependence studies may yield the nature of that competition, although again where the reactions are efficient ( $\text{HCO}_2\text{C}_2\text{H}_5$ ,  $\text{CH}_2\text{CCH}_2$ ), little change in the product distribution would be expected.

Charge transfer is observed in both cases where it is energetically possible ( $\text{NO}$ ,  $\text{C}_2\text{H}_5\text{SH}$ ), although it is a very minor product (5%) of the  $\text{C}_2\text{H}_5\text{SH}$  reaction. That charge transfer from  $\text{S}_2^+$  is not observed in the reactions with  $\text{CH}_3\text{SH}$  and  $(\text{C}_2\text{H}_5)_2\text{O}$ , which have ionization potentials only slightly higher (9.44 eV and 9.51 eV, respectively [25]) than that of  $\text{S}_2$  (9.36 eV [12]), provides additional evidence that the  $\text{S}_2^+$  is in its ground vibronic state. In the slow reaction with  $\text{NH}_3$ , the secondary product  $\text{NH}_4^+$  increases as though it were the primary product, indicating rapid proton transfer from the true primary product or products after their formation. Direct charge transfer from  $\text{S}_2^+$  to  $\text{NH}_3$  is endothermic by  $18.5 \text{ kcal mol}^{-1}$  (based on thermodynamic data obtained from [25]), and indeed,  $\text{NH}_3^+$  is not observed except for a minute fraction which can only be due to the

92% charge transfer channel of the  $\text{S}^+$  reaction [3]. The primary products of the reaction of  $\text{S}_2^+$  with  $\text{NH}_3$  have not been detected, as will be discussed below. In the case of the  $\text{NO}_2$  reaction, a small 3% 'charge transfer' channel is observed, 40% of which can be accounted for by the  $\text{S}^+$  reaction. The direct charge transfer from  $\text{S}_2^+$  to  $\text{NO}_2$  is endothermic by  $9.1 \text{ kcal mol}^{-1}$ . Since the  $\text{NO}_2$  reagent is  $\geq 99.5$  mole% pure (Matheson), the observed channel is unlikely to arise from reactions of  $\text{S}_2^+$  with reagent impurities. A possible source of this apparent 'charge transfer' is the direct reaction of  $\text{S}_2^+$  with residual dimer  $\text{N}_2\text{O}_4$ , e.g.

The equilibrium concentration of  $\text{N}_2\text{O}_4$  required to account for the remaining  $\text{NO}_2^+$  signal is about 0.2 mole% of the total  $\text{NO}_2/\text{N}_2\text{O}_4$  concentration. Although the equilibrium concentration of  $\text{N}_2\text{O}_4$  in the flow tube at the highest  $\text{NO}_2$  flows employed is calculated to be less than 0.001 mole% of the total  $\text{NO}_2/\text{N}_2\text{O}_4$  concentration, the  $\text{N}_2\text{O}_4$  concentration in the inlet flow line is much higher, of the order of 20 mole%. Thus, a sufficient non-equilibrium concentration of  $\text{N}_2\text{O}_4$  could be available in the vicinity of the inlet ring port for reaction (5) to produce the small observed  $\text{NO}_2^+$  signal. Alternatively, it is known that  $\text{NO}_2$  undergoes efficient dissociative adsorption onto stainless steel surfaces [30,31], producing  $\text{NO}(\text{gas})$  and adsorbed atomic oxygen.  $\text{NO}_2$  reacts with the adsorbed O to form  $\text{NO}_3$ , which could then desorb and react with  $\text{S}_2^+$ :

where the reaction enthalpy has been calculated from data in references [25] and [32]. Neither reaction (5) nor reaction (6) has been studied experimentally.

The production of neutral  $\text{HS}_2$ , or thiosulfeno, is an interesting feature of the data; in many of the reactions (with  $\text{CH}_3\text{CHCH}_2$ ,  $\text{C}_3\text{H}_8$ ,  $\text{CH}_3\text{OH}$ ,  $\text{C}_2\text{H}_5\text{OH}$ ,  $\text{CH}_3\text{SH}$ ,  $\text{C}_2\text{H}_5\text{SH}$ ,  $(\text{CH}_3)_2\text{O}$ ,

The ionization potential (IP) of S<sub>2</sub> is 9.36 eV for comparison [12].

<sup>a</sup>Thermodynamic values are generally based on data from the compilation of Lias et al. [25]. Exceptions are  $\Delta H_f^{\circ 298}(\text{HS}_2)$ , which is assumed to be approximately  $22.1 \pm 1$  kcal mol<sup>-1</sup>, after the estimate of Benson [26]; and  $\Delta H_f$  (C<sub>2</sub>H<sub>4</sub>S<sub>2</sub><sup>+</sup>), which has been obtained from the ab initio calculations of Ekern et al. [27]; heats of reaction based on these values are labeled 'est.'. In cases where the product identities are ambiguous, the given heats of reaction are for the least energetically favorable isomeric combinations among the suggested products, as indicated by the ≤ sign.

<sup>b</sup>Effective binary rate coefficients are given for ternary reactions at ~0.5 torr carrier pressure (see text).

<sup>c</sup>Rate coefficients given for the reactions of S<sub>2</sub><sup>+</sup> with HCO<sub>2</sub>H and C<sub>2</sub>H<sub>5</sub>CO<sub>2</sub>H are approximate values (see text).

<sup>d</sup>Collisional rate coefficients are calculated from the variational transition state theory of Su and Chesnavich [28].

<sup>e</sup>Products of binary reactions are written in empirical form, except where reaction energetics renders the structure of the product unequivocal. Association products are written as loosely-bound complexes of the reactant with S<sub>2</sub><sup>+</sup>, to distinguish them visually from the binary products. Unless otherwise indicated (footnote<sup>f</sup>), neutral products are unequivocal from the reaction energetics.

<sup>f</sup>Suggested neutral product(s); others may be possible.

(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>O, CH<sub>3</sub>CHO, and C<sub>2</sub>H<sub>5</sub>CHO), it is unequivocally the only energetically possible neutral product of its respective channel. In three of these reactions (with C<sub>3</sub>H<sub>8</sub>, CH<sub>3</sub>OH, and C<sub>2</sub>H<sub>5</sub>OH), H<sub>2</sub>S<sub>2</sub><sup>+</sup>, i.e. protonated HS<sub>2</sub>, is produced in parallel with HS<sub>2</sub> as the only competing channel; thus, there are channels with the proton residing on either of the product fragments. Only in the case of C<sub>2</sub>H<sub>6</sub> is the H<sub>2</sub>S<sub>2</sub><sup>+</sup> product seen alone. These situations can be rationalized by considering that the reaction proceeds through an initial hydride abstraction

with the intermediate having the form of the proton bound complex (X...H<sup>+</sup>...HS<sub>2</sub>). Whether this fragments to XH<sup>+</sup> or H<sub>2</sub>S<sub>2</sub><sup>+</sup> then depends on which neutral fragment has the larger proton affinity. Unfortunately, the proton affinity of HS<sub>2</sub> is not known. However, from a study of Table 2, it can be seen that for X with proton affinities greater than ~180 kcal mol<sup>-1</sup>, the proton mostly

resides with X, and thus neutral HS<sub>2</sub> is produced. For the CH<sub>3</sub>OH and C<sub>3</sub>H<sub>8</sub> reactions, the proton affinity of X (CH<sub>2</sub>O and CH<sub>3</sub>CHCH<sub>2</sub>) is 170.4 and 179.6 kcal mol<sup>-1</sup>, respectively, and since both XH<sup>+</sup> and H<sub>2</sub>S<sub>2</sub><sup>+</sup> are observed, with H<sub>2</sub>S<sub>2</sub><sup>+</sup> being dominant in the former reaction and minor in the latter reaction, this implies that the proton affinity of HS<sub>2</sub> is roughly 175 kcal mol<sup>-1</sup>, which is simply the average of these neighboring proton affinities; a more refined estimate would require the calculation of the accessible state densities of the competing exit channels in the proton-bound complex. Now, since C<sub>2</sub>H<sub>4</sub> (X in the C<sub>2</sub>H<sub>6</sub> reaction) has a proton affinity of 162.6 kcal mol<sup>-1</sup>, the proton will reside with the HS<sub>2</sub>, as is observed. In the reaction with CH<sub>3</sub>SH, X is most probably CH<sub>2</sub>S (thioformaldehyde). CH<sub>3</sub>S<sup>+</sup>/CH<sub>2</sub>SH<sup>+</sup> is the 100% reaction product (see Eq. (4)), i.e. no H<sub>2</sub>S<sub>2</sub><sup>+</sup> is observed, as expected from the proton affinity of thioformaldehyde (181.6 kcal mol<sup>-1</sup>).

Additional understanding of the reactivity of S<sub>2</sub><sup>+</sup> ions can be obtained by comparing the reac-

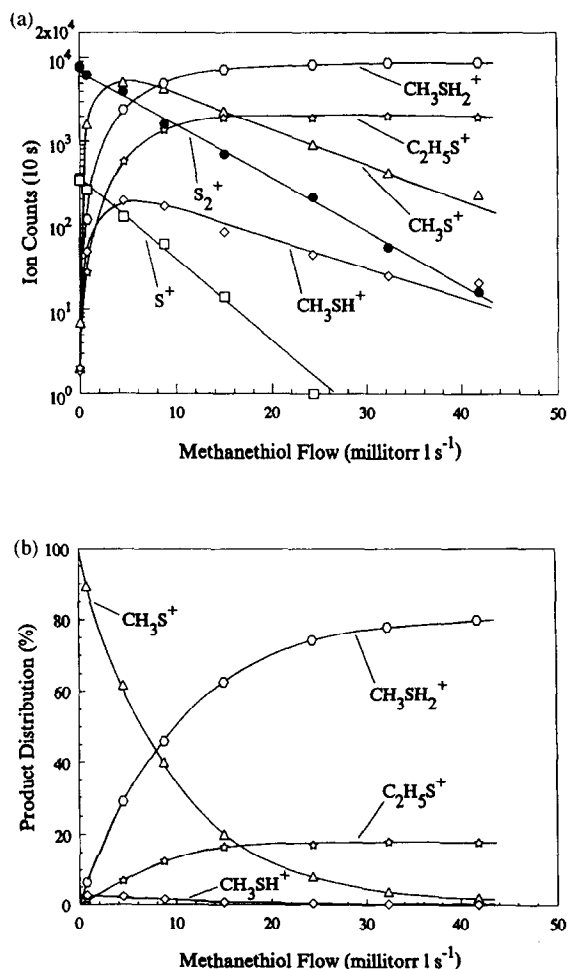

Fig. 1. (a) Variation of the  $S_2^+$  and ion product count rates with  $CH_3SH$  flow and (b) percentages of the ion products as a function of  $CH_3SH$  flow. In (a), the  $S_2^+$  decline is linear over more than two orders of magnitude. The reaction of the small  $S^+$  impurity, which is due to collisional break-up of  $S_2^+$  on injection into the flow tube, is the source of the small charge transfer channel shown in the figure. From (b), it can be seen that  $CH_3S^+/CH_2SH^+$  is the only primary product and this reacts further to give both  $CH_3SH_2^+$  ( $+CH_2S$ ) and  $C_2H_5S^+$  ( $+H_2S$ ). The data are not corrected for mass discrimination in the detection system. The rate coefficient and ion product distribution from these and the other data are listed in Table 1.

tivities and ion product distributions for the different classes of organic compounds in Table 1.

### 3.1. Inorganic

The reactions are simple for these species and

most have been studied previously [4,5]. Niedner-Schatteburg et al. [4], using an FT-ICR, also found  $H_2$  to be unreactive with  $S_2^+$  and, in a later paper [5] obtained rate coefficients of  $7.1(-12)$ ,  $3.5(-10)$  and  $1.5(-12)$   $cm^3 s^{-1}$  for  $NO$ ,  $NO_2$  and  $NH_3$ , respectively. The  $NO$  and  $NH_3$  values are very different from the present values (by at least an order of magnitude; see Table 1). That the rate coefficient for  $NO_2$  was only about a factor of 3 different is not unreasonable, considering the difficulties with these gases in the ICR study. We have no explanation for the other differences. Since none of the other reactions in the present study have been investigated previously, the rate coefficient of the straightforward reaction

which had been determined previously [3], was measured as a reproducibility check, under experimental conditions identical to those for the  $S_2^+$  studies, except that  $CS^+$  was selected from the ion source instead of  $S_2^+$ . A value of  $4.5(-10)$   $cm^3 s^{-1}$  was obtained for the rate coefficient, in excellent agreement with the literature value of  $4.3(-10)$   $cm^3 s^{-1}$  [3].

For the reaction of  $S_2^+$  with  $NH_3$ , Schindler et al. [5] report the endothermic charge-transfer product  $NH_3^+$ , which we do not observe, as was discussed above. These authors report the same products as the present study for the  $NO_2$  reaction, but they do not give a product distribution, nor any explanation for the apparent endothermic charge-transfer from  $S_2^+$  to  $NO_2$ ; we have discussed possible sources of this apparent 'charge transfer' channel for our experimental situation above.

The source of the  $NH_4^+$  which behaves as though it were the primary product of the  $NH_3$  reaction remains elusive. Better than unit mass resolution was employed in this particular study, both in the SIFT quadrupole mass filter and in the detection mass spectrometer, so that neighboring mass peaks, such as  $NH_3^+$  and  $NH_4^+$ , were well resolved, and no isotopes of the parent ion other than  $^{32}S_2^+$  were permitted into the flow tube. Thus, if possible primary products such as

Table 2

Proton affinities of the suggested neutral products and product distributions for the reactions of  $S_2^+$  leading to the probable formation of  $HS_2$  or  $H_2S_2^+$ <sup>a</sup>

Reactant, $H_2X$	Identity of X	Proton affinity of X (kcal mol <sup>-1</sup> )	Product distribution (%)

	$C_3H_4O^{e,f}$	190.5, 199.4	0	85

The proton affinity of  $HS_2$  is estimated to be  $\sim 175$  kcal mol<sup>-1</sup> (see text).

<sup>a</sup>Proton affinity values are taken from the NIST database of Hunter and Lias [33].

<sup>b</sup>Proton affinities for propyne, allene, and cyclopropene, respectively.

<sup>c</sup>Proton affinity unavailable.

<sup>d</sup>Oxirane.

<sup>e</sup>Proton affinities for 2-propenal and methylketene, respectively.

<sup>f</sup>Plausible neutral products formed along with  $HS_2$  in these channels are among  $H_2$ ,  $CO$ ,  $CH_4$ ,  $CH_2O$ ,  $CH_3CHO$ , and  $CH_2CHOH$ , with respective proton affinities in kcal mol<sup>-1</sup> of 100.9, 141.7, 129.9, 170.4, 183.8, and not available [33] (see text and Table 1).

$HS_2^+$  or  $NH_2^+$  were present, they would not have been masked by  $S_2^+$  or  $NH_3^+$  counts, respectively, in the mass spectral scan. Moreover, reactions of  $S_2^+$  with  $NH_3$  to form  $NH_2^+$ ,  $HS_2^+$ , or  $H_2S_2^+$  are all highly endothermic ( $> 50$  kcal mol<sup>-1</sup>) from consideration of the reaction energetics (a lower limit of  $\Delta H_f^\circ(HS_2^+)$  was estimated to be  $\sim 246$  kcal mol<sup>-1</sup> from the observation, made in a separate study in this laboratory, that  $HS_2^+$  transfers a proton to  $OCS$  (proton affinity = 150.2 kcal mol<sup>-1</sup>);  $\Delta H_f^\circ(HS_2)$  was taken to be  $\sim 22.1$  kcal mol<sup>-1</sup> [26]). Reaction to form  $H_3S^+$  is also endothermic, by nearly as much as the direct charge transfer from  $S_2^+$  to  $NH_3$ . Thus, a likely candidate for the primary product is not immediately apparent. The primary reaction is slow ( $k^{(2)} = 1.6(-11)$  cm<sup>3</sup> s<sup>-1</sup>; see Table 1). If, as seems likely, the

secondary reaction to form  $NH_4^+$  is a rapid proton-transfer to  $NH_3$  near the gas-kinetic limit, the maximum signal of the primary ion is certainly less than 1% of the parent ion signal, and therefore difficult to detect at the high resolution necessary to study this reaction.

### 3.2. Hydrocarbons

The reactions of  $S_2^+$  with the hydrocarbons in this study show two strikingly different general types of reactivity, depending on whether the hydrocarbon is saturated or unsaturated. In reactions with the alkanes ( $C_2H_6$  and  $C_3H_8$ ),  $S_2^+$  abstracts either  $H^-$  or  $H_2$ , and does not associate. In reactions with the alkenes ( $C_2H_4$ ,  $CH_2CCH_2$ , and  $CH_3CHCH_2$ ), association is the

dominant channel (100%, 65%, and 60%, respectively), and for allene and propylene, the binary channel products all indicate extensive structural rearrangement in the activated complex. For example, the second largest channel (20%) for allene leads to the interesting product  $\text{CS}_2^+$ , indicating the abstraction of atomic carbon from allene to leave ethylene. Similarly, the second largest channel (15%) for propylene leads to  $\text{CH}_2\text{S}_2^+$ , also leaving ethylene as the neutral fragment; thus, these two channels appear to be analogous. All of the remaining channels of both the allene and the propylene reactions are minor (about 5% each), and all lead to the formation of ion products containing only one sulfur atom, thereby indicating cleavage of the 5.38 eV (124 kcal mol<sup>-1</sup>) S–S bond of  $\text{S}_2^+$  [12]. These are the only reactions in this study for which such cleavage occurs. Since association is an important product of the rapid reactions of  $\text{S}_2^+$  with the alkenes, the intermediate complex is probably long-lived and thus tightly-bonded, allowing time for collisional stabilization. That the binary channels leading to extensive molecular reorganization occur in parallel with association indicates that, although they are efficient, the binary processes do not occur on a short time scale, but rather require substantial exploration of the potential surface of the intermediate complex to locate the exit channels. The association of  $\text{S}_2^+$  with pi-bonded systems such as alkenes and carbonyls is a very persistent feature of its chemistry, and will be noted where it occurs in the discussions that follow.

Except for  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_6$ , the hydrocarbons react with  $\text{S}_2^+$  at or near the collisional rate. The reaction with  $\text{C}_2\text{H}_6$  to form  $\text{H}_2\text{S}_2^+$  is apparently endothermic by about 4 kcal mol<sup>-1</sup>, but its reactivity cannot be explained simply by the high-energy tail of the thermal Boltzmann distribution. The measured rate coefficient,  $k_{\text{exp}}^{(2)}$ , is  $3.2(-11)$  cm<sup>3</sup> s<sup>-1</sup>, which when compared to the collisional rate coefficient,  $k_{\text{TST}}^{(2)}$ , of  $1.1(-9)$  cm<sup>3</sup> s<sup>-1</sup> calculated from the variational transition state theory of Su and Chesnavich [28], could imply an endothermicity as large as 2.1 kcal mol<sup>-1</sup> (determined using the Arrhenius-type expression  $k_{\text{exp}}^{(2)} = k_{\text{TST}}^{(2)} \exp(-\Delta H_{\text{rxn}}^\circ/RT)$ ). Although the discrepancy could be explained if the thermal energy

contained in the 18 vibrational modes of ethane is utilized, the reaction complex is unlikely to have access to much of this energy, particularly since  $\text{S}_2^+$  and ethane are not observed to associate, and therefore are not strongly bonded in the intermediate complex. A more likely explanation is an inaccuracy in the literature value for the heat of formation of  $\text{H}_2\text{S}_2^+$ , which is given as 218 kcal mol<sup>-1</sup> in the Lias et al. compilation [25]. This value is based on the vertical ionization potential of neutral  $\text{H}_2\text{S}_2$ , which was deduced to be 9.3 eV (214 kcal mol<sup>-1</sup>) from the photoelectron spectrum of  $\text{H}_2\text{S}_2$  recorded by Wagner and Bock [34]. A small error in the extrapolation of the lowest-energy photoelectron peak to the energy axis can lead to a slight inaccuracy in the determination of the first ionization potential; indeed, a mere 1% adjustment of the ionization potential of  $\text{H}_2\text{S}_2$  to 9.2 eV (212 kcal mol<sup>-1</sup>) completely accounts for the apparent discrepancy. Thus, the current literature value for the heat of formation of  $\text{H}_2\text{S}_2^+$  appears to be slightly too high (by at least 2 kcal mol<sup>-1</sup>).

Where  $\text{HS}_2$  appears as a neutral product, in the hydrocarbon reactions and in the others discussed below, reaction enthalpies are calculated using the estimate for the heat of formation,  $\Delta H_f^{\circ 298}(\text{HS}_2)$ , of  $22.1 \pm 1$  kcal mol<sup>-1</sup> made by Benson [26]. This value generally gives negative enthalpies of reaction for the channels leading presumably to  $\text{HS}_2$  in the present study. Aside from several spectroscopic studies, very little is known about the thiosulfeno radical and its chemistry [35–37].

### 3.3. Alcohols, thiols, ethers and aldehydes

Except for the small exothermic charge transfer channel with  $\text{C}_2\text{H}_5\text{SH}$ , all of the reactions studied with these classes of compound proceed by hydride abstraction or  $\text{H}_2$  abstraction to form  $\text{HS}_2$  or its protonated form,  $\text{H}_2\text{S}_2^+$ , respectively. These are the reactions involving the almost energy-resonant proton-bound complexes discussed above. Note that the proton affinities of the X fragments of the hydride abstractions (see the mechanism in Eq. (5) and Table 2) other than the methanol reaction are greater than 181 kcal mol<sup>-1</sup>

where they can be determined, and that in all of these reactions, except with ethanol, the products are always  $HX^+$  and  $HS_2$  (see Table 2). That the  $HX^+$  fragments are the protonated forms of stable neutral molecules is supported by the fact that the ion product of hydride abstraction with  $CH_3OH$  must be protonated formaldehyde,  $CH_2OH^+$ , and not the methoxy cation,  $CH_3O^+$ , by reason of the reaction energetics; and thus, in the channel of this reaction leading to  $H_2S_2^+$ , the neutral fragment is likely to be  $CH_2O$  and not  $CO + H_2$ , which is also energetically possible. Presumably, reaction mechanisms are analogous for the chemically similar species, e.g. the alcohols and thiols, and the protonated aldehydes and thioaldehydes respectively are formed where they are not necessarily dictated by reaction energetics.

The reactions are all fast, generally at or near the collisional rate. That the reactions with the smaller reactants ( $CH_3OH$ ,  $CH_3SH$ ) are less rapid may be a feature of the shorter lifetime of the intermediate complex in these cases, due to the smaller number of vibrational modes in which the energy of the association can be dissipated. Thus, there may not be time for the hydride ion abstraction step of the mechanism (Eq. (5)) to occur for every collision event.

### 3.4. Acetone

Acetone is the only ketone reacted with  $S_2^+$  in the current study. It rapidly associates, with a rate coefficient of  $1.4(-9) \text{ cm}^3 \text{ s}^{-1}$ , about half of the collisional rate. More reactions of  $S_2^+$  with ketones need to be performed before any trends in their reactivity can be assessed. However, the fact that  $S_2^+$  associates with acetone provides additional evidence for the strong interaction of this ion with pi-bonded systems. In every case in which  $S_2^+$  associates, it is with compounds that have either a carbonyl or an alkene functional group. Among such compounds,  $S_2^+$  only fails to associate with the aldehydes and the largest esters, i.e. the propionates (see below and also Table 1).

### 3.5. Carboxylic acids and esters; ( $R-CO_2-R'$ ; see Table 1)

With the carboxylic acids and esters, the most

complex and most highly-oxidized reactants considered in the present study, the prevalent themes of association and hydride abstraction by  $S_2^+$  are again observed, with patterns of reactivity governed in a discernible fashion by the extent of alkyl substitution of the R and R' moieties. Tendency to associate decreases dramatically with increasing substitution of the carbon-bonded moiety, R, in the  $\sim 0.5$  torr carrier gas environment employed in these studies. Association is the only channel for the smallest formates,  $HCO_2H$  and  $HCO_2CH_3$ , and although  $HCO_2C_2H_5$  has three binary reaction channels, association accounts for 50% of its reactivity with  $S_2^+$ . Association accounts for 10% to 25% of the reactivity of the acetates ( $R = CH_3$ ), and is negligible for the propionates ( $R = C_2H_5$ ) at the carrier pressures employed, although trace amounts of the associated product are indicated in the mass spectra of the propionate reactions. The reverse trend occurs for increasing substitution of the oxygen-bonded moiety, R'. The effective bimolecular rate coefficients of the association channels for  $HCO_2H$ ,  $HCO_2CH_3$ , and  $HCO_2C_2H_5$ , respectively, are  $\sim 5(-11)$ ,  $3.9(-10)$ , and  $7.5(-10) \text{ cm}^3 \text{ s}^{-1}$  (see Table 1). Similarly, the effective rates of association for the acetates with increasing R' substitution are  $1.3(-10)$ ,  $3.0(-10)$ , and  $4.0(-10) \text{ cm}^3 \text{ s}^{-1}$ , respectively. The increase in association with increase in the complexity of the intermediate complex is consistent with the increase in the number of vibrational degrees of freedom in which the energy of association can be dissipated. This increases the lifetime against unimolecular decomposition, and therefore, the probability of collisional stabilization. Note that the rate coefficient for the reaction with  $HCO_2H$  is given as an approximate value, due to the difficulty of measuring a small rate coefficient with a dilute mixture of 2% formic acid in helium. The rate coefficient for the reaction with  $C_2H_5CO_2H$  is also given as approximate, due to difficulties in the preparation of propionic acid/helium mixtures, because of the low vapor pressure of propionic acid at 298 K.

The trend of decreasing association with increasing substitution of the R moiety could be explained, at least in part, by the occurrence of binary channels resulting in the formation of the

highly stable acetyl cation ( $\text{CH}_3\text{CO}^+$ ) and propionyl cation ( $\text{C}_2\text{H}_5\text{CO}^+$ ) in the acetate and propionate reactions, respectively. These species, which can be considered the protonated forms of ketene and methylketene, respectively, are ubiquitous products of the reactions with the acetates and propionates, and in five of the six reactions considered, they are the dominant products by a large margin (75–100% of the reaction products — see Table 1). Thus, where they can proceed, binary channels leading to  $\text{CH}_3\text{CO}^+$  or  $\text{C}_2\text{H}_5\text{CO}^+$  might simply occur on a time scale shorter than the ternary association. Note that in the reactions with  $\text{CH}_3\text{CO}_2\text{H}$  and  $\text{C}_2\text{H}_5\text{CO}_2\text{H}$ , the respective product channels leading to  $\text{CH}_3\text{CO}^+$  and  $\text{C}_2\text{H}_5\text{CO}^+$  demand by reason of reaction energetics that the neutral fragment be some form of the molecule  $\text{HS}_2\text{O}$ , and that this molecule must have a heat of formation of  $-13 \text{ kcal mol}^{-1}$  for the reaction with  $\text{CH}_3\text{COOH}$  to be thermoneutral, using currently available heats of formation for the reactants and products [25].  $\text{HS}_2\text{O}$  could be a sulfur analogue of  $\text{HSO}_2$ , which has a heat of formation of  $-53 \text{ kcal mol}^{-1}$  at 298 K, according to an ab initio study by Boyd et al. [38]. Thus, although thermodynamic information on the  $\text{HS}_2\text{O}$  molecule is not available, it seems plausible that its heat of formation is low enough to satisfy the energetics in the  $\text{CH}_3\text{CO}_2\text{H}$  and  $\text{C}_2\text{H}_5\text{CO}_2\text{H}$  reactions.

In the other reactions leading to protonated ketene ( $\text{CH}_3\text{CO}^+$ ) or protonated methylketene ( $\text{C}_2\text{H}_5\text{CO}^+$ ) channels,  $\text{HS}_2$  is a likely neutral product in every case, although insufficient thermodynamic information, and the multiplicity of possible neutral products, have prevented the definite determination of the neutral products for these channels. If  $\text{HS}_2$  is indeed formed, then the remaining plausible neutral products for these channels include  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CH}_4$ ,  $\text{CH}_2\text{O}$ ,  $\text{CH}_3\text{CHO}$ , and  $\text{CH}_2\text{CHOH}$ , all of whose proton affinities (except for vinyl alcohol, for which the proton affinity is unavailable) are significantly lower than those of ketene and methylketene (see Table 2). Thus, as is observed, the proton should reside with the product that has the highest proton affinity in these reaction channels, in accordance with the mechanism of Eq. (5). Hydride

abstraction is also observed in the reactions of every ethyl ester ( $\text{RCO}_2\text{C}_2\text{H}_5$ ), presumably leading to the protonated vinyl ester in these cases. Although again it seems certain that the neutral product is  $\text{HS}_2$ , insufficient thermodynamic information about the ion prevents the unambiguous determination of the neutral product in these cases.

Ethyl formate ( $\text{HCO}_2\text{C}_2\text{H}_5$ ) is the only reactant among the carboxylic acids and esters which shows additional product channels other than those discussed above. A 15% channel, leading to  $\text{C}_2\text{H}_5\text{O}^+$  and the presumptive neutral products  $\text{CO}$  and  $\text{HS}_2$ , is observed; the ion product was distinguished from the three possible ion products of the reaction at  $m/z = 45$  by careful inspection of the isotope ratio. Note that the  $\text{C}_2\text{H}_5\text{O}^+$  product of this channel is possibly of the same isomeric form as the  $\text{C}_2\text{H}_5\text{O}^+$  product of the ethanol reaction. Additionally, an interesting 5% channel is observed with  $\text{HCO}_2\text{C}_2\text{H}_5$  leading to  $\text{C}_2\text{H}_4\text{S}_2^+$ , which has the same empirical formula as the association product of ethylene with  $\text{S}_2^+$ . The occurrence of this product with  $\text{HCO}_2\text{C}_2\text{H}_5$  implies that the ethyl moiety has some of the qualities of a vinyl group in the resonance structures of  $\text{HCO}_2\text{C}_2\text{H}_5$ , so that  $\text{S}_2^+$  interacts with the moiety in a way similar to its association with ethylene. Possible structures for the  $\text{C}_2\text{H}_4\text{S}_2^+$  cation and their relative energies have been investigated in an experimental and ab initio study of the reactions of thiirane radical cation with thiirane by Ekern et al. [27].

It is interesting to compare the reactivity of  $\text{S}_2^+$  with that of the analogous oxygenated ions  $\text{SO}^+$  and  $\text{O}_2^+$  as given in the literature [2,3]. Very few data are available for  $\text{SO}^+$  with the molecules in the present study (only for  $\text{H}_2$ ,  $\text{CO}$  and  $\text{NH}_3$ ). Both  $\text{SO}^+$  and  $\text{O}_2^+$  are unreactive with  $\text{CO}$  ( $< 1(-12) \text{ cm}^3 \text{ s}^{-1}$  and no reaction, respectively), as is  $\text{S}_2^+$ . With  $\text{NH}_3$ , both react similarly by rapid charge transfer, which is endothermic for  $\text{S}_2^+$ . In all of the other reactions that have previously been studied (with  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{C}_2\text{H}_4$ ,  $\text{C}_2\text{H}_6$ ,  $\text{CH}_3\text{OH}$  and  $\text{HCO}_2\text{H}$ ),  $\text{O}_2^+$ , unlike  $\text{S}_2^+$ , generally reacts rapidly by charge transfer by virtue of the larger ionization potential of  $\text{O}_2$  (12.07 eV relative to 9.36 eV for  $\text{S}_2$  [25]). Only in the cases of

$\text{CH}_3\text{OH}$  and  $\text{HCO}_2\text{H}$  is there another reaction channel, hydride abstraction, yielding the neutral product  $\text{HO}_2$  analogous to the common product  $\text{HS}_2$  in the present studies, although this does not occur in the  $\text{HCO}_2\text{H}$  reaction with  $\text{S}_2^+$ .

#### 4. Conclusions

The present study of the reactions of  $\text{S}_2^+$  with a series of hydrocarbons, alcohols, thiols, aldehydes, ethers, carboxylic acids and esters has shown the general features of association and the production of neutral  $\text{HS}_2$ , the latter of which is believed to result from the fragmentation of proton-bound complexes,  $(\text{X}\cdots\text{H}^+\cdots\text{HS}_2)$ . S-atom insertion is observed only with the alkenes, in contrast to  $\text{S}^+$  reactions with similar species [1–3], for which insertion channels are common; this is probably a result of the strength of the  $\text{S}_2^+$  bond. However, the association reactions result in the incorporation of  $\text{S}_2$  and this could be a route to  $\text{S}_2$ -containing species in the interstellar medium (ism). Note that the weakly-bonded association complexes may only be able to isomerize to specific more strongly bonded forms, so that all possible isomers should not be assumed to exist in the ism. This has recently been discussed with respect to the isomeric forms of  $\text{CH}_3\text{O}_2^+$ ,  $\text{CH}_5\text{O}^+$  and  $\text{C}_2\text{H}_7\text{O}^+$  [24,39]. No species containing  $\text{S}_2$  have yet been detected in the ism and these should be searched for. In particular, interstellar thio-sulfeno ( $\text{HS}_2$ ) should be searched for, since it is a common product in the  $\text{S}_2^+$  reactions. In addition, where fragmentation of the proton-bound complex results in  $\text{H}_2\text{S}_2^+$  production, more  $\text{HS}_2$  is likely to be produced following dissociative recombination with electrons,

(this is not the only energetically possible channel). Note that a recent study of the dissociative recombination of  $\text{H}_3\text{O}^+$  has shown that only a small proportion of the recombinations result in  $\text{H} + \text{H}_2\text{O}$  (5%) with further fragmentation to two atoms and a diatomic molecule in 60% of the cases [40]. Thus, by analogy, other dissociative channels might be expected in the case of  $\text{H}_2\text{S}_2^+$ .
